### ABSTRACT

Wavelength dependence of interstellar linear polarization has been observed for about 180 stars, mostly southern, in the *UBVR* spectral regions. A multichannel polarimeter-photometer, in which spectral regions are separated by dichroic filters, was used. Normalized wavelength dependence of interstellar linear polarization  $p$  follows closely a single empirical curve  $p(\lambda)/p_{\max} = \exp[-1.15 \ln^2(\lambda_{\max}/\lambda)]$ , where the wavelength  $\lambda_{\max}$  at which the maximum interstellar linear polarization  $p_{\max}$  occurs takes values from  $0.45 \mu$  to  $0.8 \mu$ .

Wavelength  $\lambda_{\max}$  is well correlated with the ratios of color excesses  $E_{V-K}/E_{B-V}$ ,  $E_{V-K}/E_{V-R}$ , and  $E_{V-I}/E_{V-R}$ . These correlations indicate that the ratio  $R$  of total to selective interstellar extinction can be found for any individual star from the relationship  $R = 5.5 \lambda_{\max}$ . Polarimetry seems to be the most practical method of estimating  $R$ . A map of distribution of  $\lambda_{\max}$  on the sky, based on values for about 350 stars, indicates several well defined regions with  $\lambda_{\max}$ , and hence  $R$ , clearly larger (or smaller) than the median value  $\lambda_{\max} = 0.545 \mu$ , corresponding to  $R = 3.0$ .

The predominance of larger than average values of  $\lambda_{\max}$  among stars nearer than 0.4 kpc and the negative correlation between  $\lambda_{\max}$  and  $E_{B-V}$  are explained by selection effects. There is evidence of negative correlation between  $\lambda_{\max}$  and  $p_{\max}/E_{B-V}$  suggested by Kruszewski. The lower limits for color excess of Praesepe, M67, and several globular clusters are set by their linear polarization. The largest known values of interstellar circular polarization,  $|q| \cong 0.06$  percent, were found in near-infrared for two stars with exceptionally small  $\lambda_{\max}$ : star No. 12 in association VI Cygni and HD 204827.

### I. INTRODUCTION

Several regions of the sky with the wavelength of maximum interstellar linear polarization either predominantly higher or predominantly lower than average have been found by Serkowski and Robertson (1969). This suggested that the wavelength dependence of interstellar polarization may be a good indicator of the variations in size of interstellar dust grains within the Galaxy. To accelerate collection of data on wavelength dependence of polarization, a new multichannel polarimeter-photometer has been constructed at Mount Stromlo Observatory. Polarimetric and photometric measurements are made with this instrument in several spectral regions simultaneously; therefore, the observing times required for attaining the desired precision of results are much shorter than with previous instruments. An observing program with this polarimeter-photometer, extending over 1 year, has almost doubled the amount of data on the wavelength dependence of interstellar polarization.

### II. MULTICHANNEL POLARIMETER-PHOTOMETER

Most of the new polarimetric observations presented in this paper were made with the polarimeter-photometer constructed in the workshops of Mount Stromlo Observatory during the year 1969. The mechanical parts were designed and made under the supervision of Mr. Bela Bodor, and the electronic parts were designed by Mr. Peter Rudge. The instrument was

used with the 61-cm (24 inch) rotatable tube telescope of Siding Spring Observatory.

The stellar light, after passing through a focal plane diaphragm, is split into two beams by a calcite Wollaston prism (fig. 1). The observations are made alternately with and without the Lyot depolarizer, consisting of two quartz plates, 2 mm and 4 mm thick, in optical contact, inserted in front of the Wollaston prism. The two beams emerging from the Wollaston prism fall on two fused silica Fabry lenses of 12 cm focal length, one of which is cemented to a quartz half-wave plate which rotates the plane of polarization by about  $90^\circ$  in the blue spectral region, so that both beams are polarized at approximately the same plane. Each of the two beams goes subsequently, at  $45^\circ$  incidence, through four dichroic filters made by Optical Coating Laboratory in Santa Rosa, California. The first filter reflects over 85 percent of wavelengths 3100–3900 Å, transmitting over 85 percent of wavelengths 4100–10,000 Å. The second filter reflects the wavelengths longer than 8200 Å, transmitting over 90 percent of the wavelengths shorter than 7800 Å. The third filter reflects  $\lambda > 6500$  Å, transmitting over 90 percent of light with  $3900 \text{ Å} < \lambda < 6300 \text{ Å}$ . Finally, the last filter reflects  $\lambda < 4900 \text{ Å}$ , transmitting  $\lambda > 5000 \text{ Å}$ . The four filters split the light into the five spectral regions close to Johnson's (1965) *UBVRI* regions.

The cathodes of the photomultipliers are cooled by blowing a stream of cold nitrogen gas, evaporated

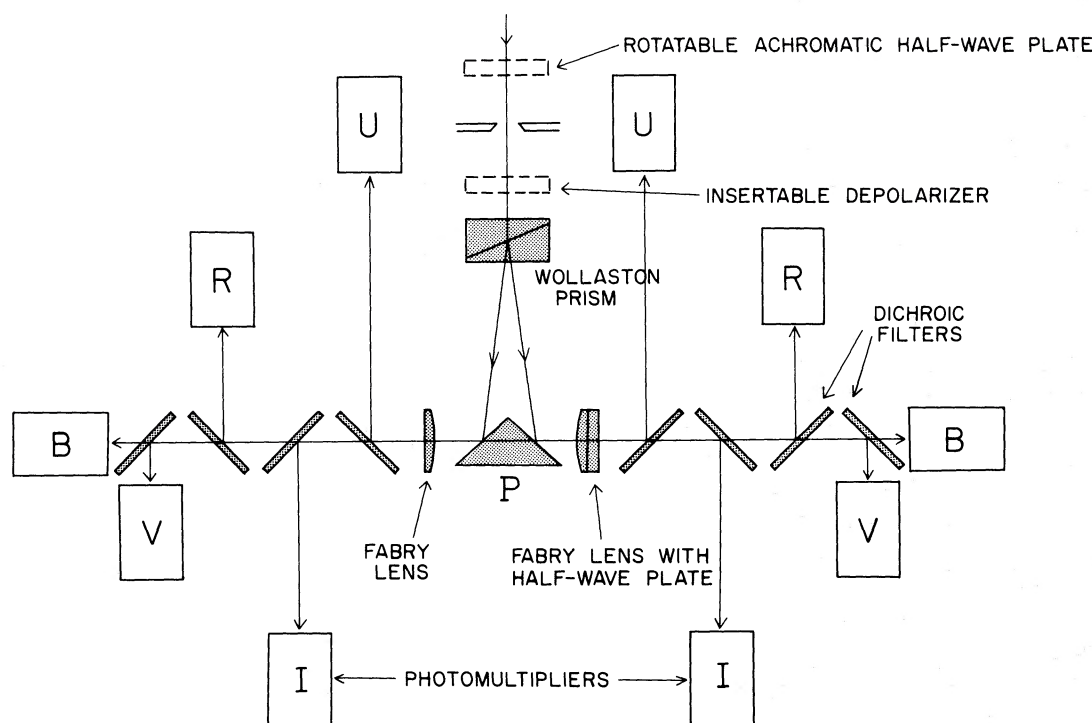

FIG. 1.—Schematic diagram of the polarimeter-photometer. Actually the axes of light beams incident on photomultipliers are in a plane perpendicular to this diagram.

from a bottle of liquid nitrogen, onto the front ends of the photomultipliers. The inside of the polarimeter is kept dry by continuous flushing with dry nitrogen. This cooling system, which is presently in operation, was not installed at the time when the observations for the present paper were made; therefore, the infrared spectral region was not used, and unrefrigerated photomultipliers were used for the remaining spectral regions: EMI 6256 (S11 cathode) for *U*, *B*, and *V*, EMI 9502 (S20 cathode) for *R*. The *U*, *B*, and *V* spectral regions approximate the standard *UBV*

regions (Johnson 1965; Matthews and Sandage 1965) while the *R* region has an effective wavelength similar to Johnson's except that its half-width is only about 1000 Å (fig. 2). In an attempt to obtain better agreement with the standard photometric system and for reducing red leaks, Schott glass filters were cemented to the photomultiplier windows: 0.75 mm UG 1 for *U* photomultipliers, 0.5 mm GG 13 and 2.5 mm Corning 5-57 for *B*, 2 mm GG13 and 1 mm BG 38 for *V*, and 1 mm RG5 for *R* photomultipliers. The red leak in the *U* spectral regions, determined by observing

FIG. 2.—The wavelength dependence of the product of the photomultiplier quantum efficiency and the transmittance of the Earth atmosphere, telescope, and polarimeter (both channels) for the four spectral regions separated by the dichroic and glass filters. The dashed lines are the response curves for standard *UBV* spectral regions (Johnson 1965; Matthews and Sandage 1963), in arbitrary units.

carbon stars, has quantum efficiency not exceeding  $10^{-3}$  percent. The dark current was negligibly small for EMI 6256 but was as large as the signal from a star of  $R \approx 8$  mag in the  $R$  spectral region; therefore, the accuracy in the latter region for fainter stars is lower than in the other spectral regions.

The signal from each of the 10 photomultipliers is fed into a separate integrator. At the end of each integration the voltages at these integrators, designed by Mr. D. G. Thomas, are consecutively measured by a digital voltmeter and recorded on punched paper tape and by an electric typewriter. Usually 20-s integrations were used for stars with  $V < 8.0$  mag, 40 s for the fainter stars. The measurements were made at four position angles of the tube of the rotatable telescope:  $0^\circ$ ,  $45^\circ$ ,  $90^\circ$ , and  $135^\circ$ . Only the nearby standard stars were observed at eight position angles, from  $0^\circ$  to  $315^\circ$ . At each position angle four integrations for a star were made (an integration without depolarizer, two integrations with depolarizer, and again without) and two for the sky background (with and without depolarizer). For bright stars the accuracy, independent of stellar magnitude, is limited by the residual atmospheric scintillation, by imperfect focusing of the Fabry lenses combined with imperfect guiding of the telescope, by a slightly wedge-shaped depolarizer, by photomultiplier fatigue, and by other instrumental errors. The atmospheric scintillation for the ratio of signals from two photomultipliers was found to amount to about 15 percent of the scintillation observed with a single photomultiplier. For the fainter stars the accuracy is limited by shot noise; for an observation consisting of sixteen 20-s integrations for a star, the mean error  $\epsilon(p)$  of the degree of linear polarization  $p$  [ $\gg \epsilon(p)$ ] equals

$$\epsilon(p) = c \cdot 10^{m/5}, \quad (1)$$

where  $m$  is the stellar magnitude in the corresponding spectral region while  $c = 0.0025$  percent for  $U > 5$  mag, 0.0016 percent for  $B > 6$  mag, 0.0027 percent for  $V > 5$  mag, and 0.0070 percent for  $4 \text{ mag} < R < 7$  mag. From these values of  $c$  and from spectrum scans with a monochromator the quantum efficiencies of the photomultiplier combined with the entire optical system, including the Earth's atmosphere, are derived (cf. Serkowski 1968) and are plotted in figure 2. Comparing these quantum efficiencies with the values supplied for the photomultipliers by the manufacturer, we find a joint transmittance of the telescope + polarimeter (both channels for each spectral region), including dichroic filters, close to 18 percent. The transmittance of all four dichroic filters for the  $B$  spectral region is about 60 percent.

The depolarizer correction factors were found by observing the stars with a Glan-Thompson prism placed at different position angles in front of the polarimeter. The adopted depolarizer correction factors  $D$  (as defined by Serkowski 1968) are listed in table 1.

There is provision for inserting a rotatable achromatic half-wave plate in front of the focal plane diaphragm of the polarimeter-photometer. With such a

half-wave plate the depolarizer will no longer be necessary, and the observing time needed to achieve the desired polarimetric accuracy will be one-fourth as long (Serkowski 1974). The half-wave plate was not used in the present observing program because sufficiently achromatic plates were not known at the time when the observations were started. For circular polarization measurements an achromatic quarter-wave plate may be inserted instead of the half-wave plate.

The multichannel instrument can be used not only as a polarimeter but also as a star-sky photometer. For this application the Wollaston prism, together with the aluminized prism  $P$  (see fig. 1) and Fabry lenses, is removed as one unit. Another unit is substituted containing a right-angle aluminized prism and Fabry lenses cemented to quartz depolarizers. Such depolarizers are needed to avoid the effect of stellar polarization on transmittance of dichroic filters. Two focal-plane diaphragms with their centers separated by 19 mm are used. The star image is placed first in one diaphragm, then in the other; the sky background in another diaphragm is measured simultaneously. The fact that filters are in the same compartment as the photomultipliers and cooled with a stream of dry nitrogen is favorable for precise photometry, as the spectral properties of dichroic and glass filters may depend on temperature (Young 1967) and humidity (Schild, Steudel, and Walther 1967). The multichannel instrument here described was used for observing the wavelength dependence of extinction by terrestrial clouds (Serkowski 1970b). As this extinction was found to be nearly neutral, the measurements of color indices are not affected by presence of thin clouds.

### III. OBSERVATIONS

The polarimetric observations of the nearby stars, which may be supposed to be unpolarized, are listed in table 2, where  $p$  is the percentage polarization and  $\theta$  the position angle of the electric vector in the equatorial coordinate system. The mean values of  $p$  and  $\theta$  obtained from the averages of the normalized Stokes parameters  $p_x = p \cos 2\theta$  and  $p_y = p \sin 2\theta$  in the blue and yellow spectral regions are also given; the observations in these two spectral regions are more accurate than those in the remaining ones. The

\* Average includes observations by Mathewson and Ford (1970a,b).

† Average includes observations by Serkowski (1968).

‡ Polarization  $p = 0.009 \pm .014\%$  (m.e.),  $\theta = 47^\circ$  was found with the Yerkes rotatable telescope by Appenzeller (1968).

published observations of the nearby stars made with the same telescope (Serkowski 1968; Mathewson and Ford 1970a, b) are included in these averages and in the averages for individual filters. Similarly as in the earlier papers (Serkowski 1968, 1974), the values of  $p$  are followed by an average of the mean errors of the normalized Stokes parameters  $p_x$  and  $p_y$  for the blue and yellow spectral regions. The number  $n$  of observations with each filter is followed by letter  $M$  for the observations made with the multichannel polarimeter, by  $T$  for those with the two-channel polarimeter (Serkowski 1968). The results listed in table 2 indicate that the values of the normalized Stokes parameters averaged over all nearby stars are zero within the limits of error; the instrumental polarization, if any, was eliminated by rotation of the telescope tube.

The stars with large interstellar linear polarization have been chosen for the present study of its wavelength dependence from the catalogs by Hall (1958) and by Mathewson and Ford (1970a). Those stars have been selected for which a single observation with the multichannel polarimeter in the yellow spectral region could be expected to give a relative mean error of percentage polarization,  $\epsilon(p)/p$ , not exceeding  $\pm 0.04$ . As can be seen from equation (1), this happens for percentage polarization

$$p > 10^{V/5}/15, \quad (2)$$

where  $V \geq 5$  is a visual magnitude. A large percentage of southern stars with known polarization fulfilling this criterion have been included in the present survey.

To find more stars suitable for study of wavelength dependence of interstellar polarization, the polarization in the yellow or blue spectral regions have been observed with a two-channel polarimeter for a number of stars with large interstellar reddening. Since for interstellar polarization  $p^V \leq 9 E_{B-V}$  (Schmidt-Kaler 1958) and, on the average,  $p^V \cong 4.5 E_{B-V}$ , our criterion (2) becomes

$$E_{B-V} > 10^{V/5}/67.5; \quad (3)$$

e.g., for  $V = 7.5$  mag this gives  $E_{B-V} > 0.47$  mag. In case of supergiants of absolute magnitude  $-7$  and reddening  $0.3 < E_{B-V} < 1.4$ , limiting a survey to stars fulfilling condition (3) is equivalent<sup>1</sup> to limiting it to stars with a distance modulus less than 13.0. The polarimetric measurements of some stars fulfilling condition (3) are listed in Table A1 in the Appendix.

Table 3 gives the individual observations of the wavelength dependence of the interstellar polarization, most of them made with the multichannel polarimeter. Some observations made by Serkowski with the two-channel polarimeter (described by Visvanathan 1966 and Serkowski 1968) before the multichannel instrument was completed are also included and marked with an asterisk following the Julian Day; the de-

polarizer corrections for these observations were calculated as described earlier (Serkowski 1970a). Individual observations for which the mean error of percentage polarization is more than twice as large as is usual for a star of given magnitude are indicated by colons.

It was noticed recently (Serkowski 1973) that observations of interstellar polarization for all the stars follow the same curve when the ratio of polarizations  $p(\lambda)/p(\lambda_{\max})$  is plotted against the ratio of the wavelength  $\lambda_{\max}$  of the maximum polarization for a given star to the wavelength  $\lambda$  at which polarization is measured. This curve is well approximated by an empirical formula

$$p/p_{\max} = \exp [-K \ln^2 (\lambda_{\max}/\lambda)], \quad (4)$$

where the constant  $K$  is the same for all stars. By taking the natural logarithm of both sides of equation (4), we obtain

$$\ln p + K(\ln \lambda)^2 = X_1 + X_2 \ln \lambda, \quad (5)$$

where

$$X_1 = \ln p_{\max} - K(\ln \lambda_{\max})^2, \quad (6)$$

$$X_2 = 2K \ln \lambda_{\max}. \quad (7)$$

Equations (5), with weights calculated from errors of individual observations, were solved for each star by least squares for the unknowns  $X_1$  and  $X_2$ , and then  $\lambda_{\max}$  and  $p_{\max}$  were found from equations (6) and (7). The solutions were repeated for different values of the constant  $K$ . The value  $K = 1.15$  was finally assumed, which fits both our observations and those made at the University of Arizona (Coyne, Gehrels, and Serkowski 1974). This value of  $K$  was used for calculating  $\lambda_{\max}$  listed in tables 3 and 5. All stars observed with our multichannel polarimeter, except those suspected of having an intrinsic component of polarization (marked with an asterisk in the first column of table 5) and except those with  $p_{\max}$  less than 1.0 percent, were used for calculating the normalized wavelength dependence of interstellar linear polarization plotted in figure 3.

All the observations of a star with a particular filter are averaged, and the averages for various stars are arranged in order of  $\lambda_{\max}/\lambda$  in groups of 20. The mean value of  $p/p_{\max}$  for each such group comprising 20 stars is denoted by an open circle in figure 3 while dots denote the averages for individual stars for which  $\lambda_{\max}/\lambda > 1.70$ . The curve shown in figure 3, calculated from equation (4), fits the observations well. Similar graphs, based on the observations made at the University of Arizona and covering a wider range of  $\lambda_{\max}/\lambda$ , were published by Coyne *et al.* (1974) and by Serkowski (1973, 1974).

The effective wavelengths  $\lambda$  entering equation (5) were calculated for the observations with the multichannel polarimeter from the response curves shown in figure 2. For calculating the inverse effective wavelengths, these response curves were multiplied,

<sup>1</sup> The distance modulus fulfills  $V - M_V - 3E_{B-V} < C - M_V$ , where, as results from inequality (3),  $C = 5 \log (67.5E_{B-V}) - 3E_{B-V} \cong 6.0 \pm 0.3$  for  $E_{B-V}$  in the interval quoted.

FIG. 3.—The normalized wavelength dependence of interstellar linear polarization derived from the observations with the Siding Spring multichannel polarimeter-photometer. The solid line is calculated from eq. (4) for  $K = 1.15$ . Every open circle is based on 20 stars, while each dot represents the observations of an individual star with a particular filter.

before plotting as a function of inverse wavelength, by the number of photons of stellar light per unit frequency interval per  $\text{cm}^2$ ,  $n_\nu = \text{const.} \cdot \lambda^3 F_\lambda$ . The flux  $F_\lambda$  was calculated for several representative stars of different reddening and spectral type from the results of the intermediate-band photometry by Mitchell and Johnson (1969), making use of the absolute calibration given in their table 2. An assumption was made that  $p(\lambda)$  is a linear function of  $\lambda^{-1}$  over each of the spectral regions. We have found that the dependence of inverse effective wavelength on stellar color index can be approximated by a linear expression

$$\lambda_{\text{eff}}^{-1} = \lambda_0^{-1} - (B - V) k_B, \quad (8)$$

for the  $B$ ,  $V$ , and  $R$  spectral regions, and by

$$\lambda_{\text{eff}}^{-1} = \lambda_0^{-1} - (U - B) k_U, \quad (9)$$

for the  $U$  spectral region. The assumed coefficients  $\lambda_0^{-1}$ ,  $k_B$ , and  $k_U$  for the polarimeters which were used for observing the wavelength dependence of interstellar polarization are given in table 4; the values for the  $UBV$  system are based on response curves by Johnson (1965) and by Matthews and Sandage (1963).

For each star the effective wavelengths have been calculated using these coefficients and the color indices for that particular star.

#### IV. SUMMARY OF DATA ON WAVELENGTH OF MAXIMUM INTERSTELLAR POLARIZATION

All the available data on the wavelength  $\lambda_{\text{max}}$  at which interstellar linear polarization takes the maximum value  $p_{\text{max}}$  are listed in table 5. The only stars with mean error of  $\lambda_{\text{max}}$  not exceeding  $\pm 0.03 \mu$  which are omitted are those 104 stars for which  $\lambda_{\text{max}}$  is given by Coyne *et al.* (1974) in their table 2 and which were observed only at the University of Arizona.

The stars are listed in table 5 in order of increasing right ascension. The MK spectral types are taken from Hiltner, Garrison, and Schild (1969), Lesh (1968), or Walborn (1972), if available; otherwise the MK type is taken from the compilations by Jaschek, Conde, and de Sierra (1964) or by Kennedy (1971). Photometry is taken from compilations by Blanco *et al.* (1968) or by Jaschek *et al.* (1972). The color excesses  $E_{B-V}$  and distance moduli  $m - M$  are calculated using the intrinsic colors and luminosity calibration by Schmidt-Kaler (1965) and assuming that visual extinction equals  $A_V = 3E_{B-V}$ . For Cepheids

\* Intrinsic polarization possible, star not used in discussion of interstellar polarization.

† Wavelength dependence of polarization inaccurate, not used in discussion.

‡ Also in Table 3.

§  $\Theta^V$  in Serkowski (1968) on J.D. 2439773 should read 5.5 instead of 4.1.

the period-luminosity relation of Sandage and Tammann (1968) was used.

The values of  $\lambda_{\max}$  and  $p_{\max}$  listed for each instrument in table 5 are the straight averages of the values of these quantities calculated for each observing night separately whenever such data are available. They are followed by the mean errors derived from the scatter of values obtained on various nights. In cases when a star was observed with a particular instrument on one or two nights only, the mean errors are derived from the fit of the measurements at different spectral regions to the curve described by equation (4). The mean errors of  $\lambda_{\max}$  referring to values derived from polarimetry at three or two spectral regions only are followed by a colon or a double colon, respectively, to indicate that these errors are determined less accurately and may be underestimated. A colon following  $\lambda_{\max}$  denotes a value based on observations from a single night. When calculating the weighted mean values of  $\lambda_{\max}$  and  $p_{\max}$ , listed in table 5, the values without colons are given full weight; those with a colon following  $\lambda_{\max}$  or its error, half weight; those with two colons, quarter weight. The mean errors listed do not influence these weights. The daggers in the first column of table 5 denote the stars for which the mean error of  $\lambda_{\max}$  exceeds  $\pm 0.03 \mu$ ; they are not used in the further discussion of interstellar polarization. The depolarization corrections described by Serkowski (1968) were applied to the observations made with the Belgrade refractor (Kruszewski 1962; Serkowski 1965b).

If a star was observed in  $B$  and  $V$  spectral regions only, the values of  $\lambda_{\max}$  were found from the following formula, resulting from equation (4),

$$\lambda_{\max} = (\lambda^V \lambda^B)^{1/2} \exp \left\{ \frac{\ln(p^V/p^B)}{2K \ln(\lambda^V/\lambda^B)} \right\}. \quad (10)$$

Substituting  $K = 1.15$  and the effective wavelengths  $\lambda^B = 0.44 \mu$  and  $\lambda^V = 0.55 \mu$ , we get

$$\lambda_{\max} = 0.49(p^V/p^B)^{1.95}. \quad (11)$$

This relationship between  $\lambda_{\max}$  and  $p^V/p^B$  is shown in figure 4 while comparison between the values of  $\lambda_{\max}$  obtained for the same stars with different instruments is shown in figure 5. No systematic differences in  $\lambda_{\max}$  between various instruments were found.

The stars for which the observed wavelength dependence of polarization may be a superposition of the effects of interstellar and intrinsic polarization have an asterisk in the first column of table 5 and are not included in the further discussion of interstellar polarization. They include the Wolf-Rayet stars and those B and A-type stars of luminosity class III, IV, or V which have emission lines in their spectra according to Bertiau and McCarthy (1969), Jaschek, Ferrer, and Jaschek (1971), or Wackerling (1970); among such stars only those for which variability of polarization with time has not been proven and polarization is not smaller than 1 percent are listed in table 5. On the

FIG. 4.—The relationships between the ratios of polarizations  $p^V/p^B$  in  $V$  and  $B$  spectral regions (solid curve and left scale) or  $p_{\max}/p^V$  (dashed curve and right scale) and the wavelength  $\lambda_{\max}$  of maximum interstellar polarization, calculated for  $\lambda^V = 0.55 \mu$  and  $\lambda^B = 0.44 \mu$ .

other hand, the Of stars and the early-type supergiants with emission lines in their spectra are not marked with an asterisk in table 5. Among the latter stars, many show evidence of variable intrinsic polarization (Serkowski 1970a, Coyne 1971) which in all known cases is small compared with interstellar polarization and has rather flat wavelength dependence. Therefore, distortion of the wavelength dependence of interstellar polarization by this intrinsic component seems to be small. Evidence of small variations in polarization with time has been found also among some early-type supergiants without emission lines. For these reasons separating the early-type supergiants without any intrinsic component of polarization is not, at this time, possible. We decided to include all the observed early-type supergiants and Of stars in our discussion of interstellar polarization.

## V. DISCUSSION

There are 364 stars listed either in table 5 of the present paper or in table 2 of Coyne *et al.* (1974) which are not marked with an asterisk in the first column of these tables and for which the mean error of  $\lambda_{\max}$  does not exceed  $\pm 0.03 \mu$ . Distribution of the stars for which galactic latitude is  $|b| \leq 25^\circ$  is shown in figure 6. Filled symbols represent the stars with wavelength  $\lambda_{\max}$  of maximum polarization less than the median value of  $0.545 \mu$ , open symbols represent those with  $\lambda_{\max} > 0.545 \mu$ . The obvious conclusion from inspecting this figure is that there are some well-defined regions on the sky within which  $\lambda_{\max}$  is smaller than the median value and other regions with  $\lambda_{\max}$  larger than the median value. In figure 6 these two types of regions are surrounded by dashed and solid lines, respectively. The largest and best defined region of low  $\lambda_{\max}$  lies along the galactic

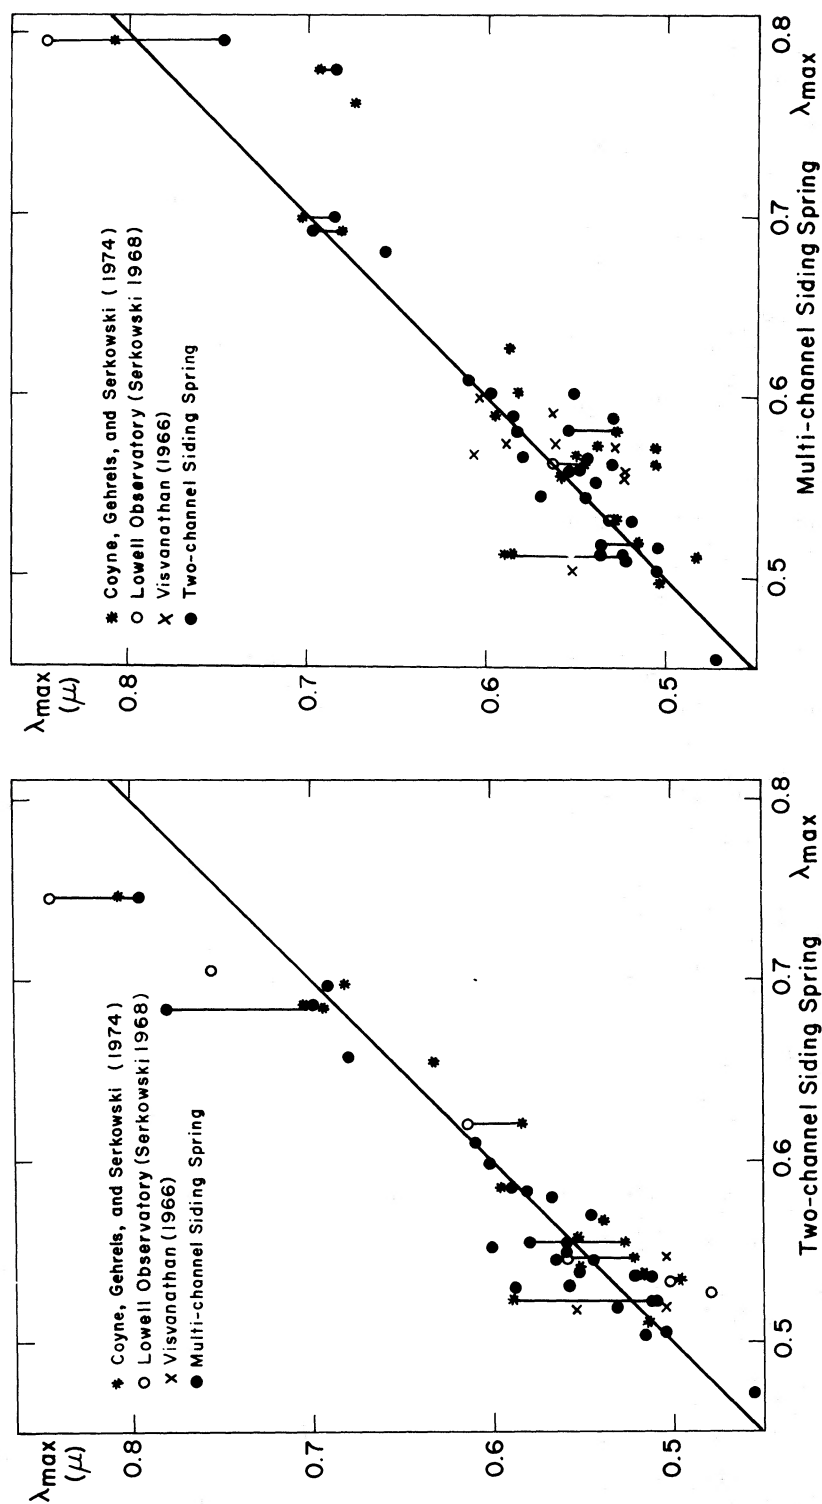

FIG. 5.—The comparison between values of the wavelength of maximum interstellar linear polarization,  $\lambda_{\max}$ , determined with the Siding Spring two-channel (a) and multichannel (b) polarimeters with those obtained for the same stars with other instruments on the basis of polarimetry at three or more spectral regions. Vertical lines join the observations of the same star.

FIG. 6.—The wavelength of maximum interstellar polarization,  $\lambda_{\max}$ , which is proportional to ratio  $R$  of total to selective extinction, plotted in galactic coordinates. Filled symbols denote the stars with  $\lambda_{\max}$  (and  $R$ ) smaller than the median value  $\lambda_{\max} = 0.545 \mu$  (corresponding to  $R = 3.0$ ); open symbols, those with  $\lambda_{\max}$  (and  $R$ ) larger than the median value. The regions in which the stars of any of these groups predominate are surrounded by dashed or solid lines, respectively. Symbols for stars nearer than 0.4 kpc ( $m - M \leq 8.0$ ) are crossed with a horizontal bar.

FIG. 7.—The correlation between the wavelength  $\lambda_{\max}$  of maximum interstellar polarization and the color excess ratio  $E_{V-I}/E_{V-R}$ . Large symbols denote observations from references 1, 2, 3, 6, and 7 in table 6. Small symbols denote less accurate photometry from other sources.

equator at longitudes  $120^\circ$ – $145^\circ$ ; that of high  $\lambda_{\max}$  lies at longitudes  $295^\circ$ – $340^\circ$ .

Symbols for stars nearer than 0.4 kpc ( $m - M \leq 8.0$ ) are crossed in figure 6 with a horizontal bar. We can see clearly that high values of  $\lambda_{\max}$  predominate for nearby stars. The median value of  $\lambda_{\max}$  for stars nearer than 0.4 kpc is  $0.570 \mu$  as compared with  $0.536 \mu$  for more distant stars. For each of these distance intervals a histogram of  $\lambda_{\max}^{-1}$  is well approximated by a Gaussian probability function with rms deviation  $\pm 0.14 \mu^{-1}$ ; a small deviation

from the Gaussian function is caused by too many stars with  $\lambda_{\max} > 0.66 \mu$ , particularly among nearby stars.

Larger  $\lambda_{\max}$  for nearby stars may be explained by a selection effect: nearby stars for which polarization is so large that  $\lambda_{\max}$  can be determined are often seen through a relatively dense dust cloud. As shown by Carrasco, Strom, and Strom (1973), the size of dust grains and  $\lambda_{\max}$  seem to be larger in denser dust clouds. There is no correlation between  $\lambda_{\max}$  and distance for stars more distant than 0.4 kpc.

It is likely that the wavelength  $\lambda_{\max}$  of maximum polarization is proportional to the average size of interstellar dust grains producing both extinction and polarization. This is indicated by the correlations between  $\lambda_{\max}$  and various ratios of color excesses (cf. Serkowski 1968, 1973). The correlation is particularly pronounced for the ratio  $E_{V-I}/E_{V-R}$  shown in figure 7 and the ratios  $E_{V-K}/E_{B-V}$  and  $E_{V-K}/E_{V-R}$  shown in figure 8. Only the stars with  $E_{V-R}$  or  $E_{B-V}$  no smaller than 0.30 mag are plotted in these figures; we believe that inaccurate photometry and intrinsic colors are mainly responsible for large scatter seen in figures 7 and 8. There seems to be no correlation between  $\lambda_{\max}$  and  $E_{V-R}/E_{B-V}$  and very little between  $\lambda_{\max}$  and  $E_{V-K}/E_{V-J}$ .

Since the ratio of total to selective extinction,  $R = A_V/E_{B-V}$ , equals approximately 1.1  $E_{V-K}/E_{B-V}$  (Carrasco *et al.* 1973), the straight line  $E_{V-K}/E_{B-V} = 5.0 \lambda_{\max}$  in figure 8a indicates that

$$R = 5.5 \lambda_{\max}; \quad (12)$$

the median value  $\lambda_{\max} = 0.545 \mu$  corresponds to  $R = 3.0$ . Measuring  $\lambda_{\max}$  may be the best method for finding the local values of the ratio of total to selective extinction.

The observational data for figures 7 and 8 are listed in table 6. New *VRI* photometry listed in this table was obtained by Serkowski with the Mount Stromlo 127-cm (50 inch) telescope in 1969 June and

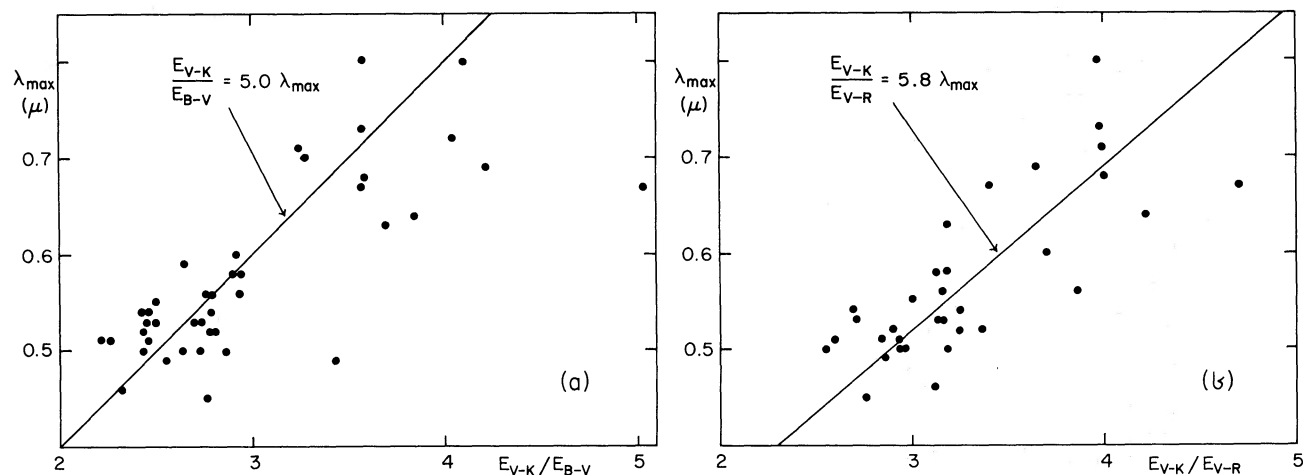

FIG. 8.—The correlation between  $\lambda_{\max}$  and the color excess ratios  $E_{V-K}/E_{B-V}$  (graph a), and  $E_{V-K}/E_{V-R}$  (graph b). The two stars falling far below the straight line in graph a are HD 164740 and 215835 (Johnson 1967).

July using equipment similar to that described in an earlier paper (Serkowski 1968); each star was observed on two or three nights. The mean errors of average  $V - R$  and  $V - I$  are about  $\pm 0.01$  and  $\pm 0.03$  mag, respectively. The photometry in the  $K$  spectral region for the stars HD 194279 and 204827 was obtained in 1972 by Serkowski using the Steward Observatory infrared photometer (Johnson and Mitchell 1962) and 229-cm (90 inch) telescope. The  $V - R$ ,  $V - I$ , and  $V - K$  intrinsic colors by Johnson (1966) are used.

There seems to be some correlation of  $\lambda_{\max}$  with  $E_{B-V}$  and with the ratio of polarization to interstellar

reddening,  $p_{\max}/E_{B-V}$ . To avoid the dependence on distance, the correlations were studied only for stars more distant than 0.4 kpc. The median values of  $\lambda_{\max}$  for intervals of  $E_{B-V}$  follow the relationship

$$\lambda_{\max} = 0.555 \mu - 0.03 E_{B-V}, \quad (13)$$

where the correlation coefficient is  $-0.19 \pm 0.07$  (m.e.). This correlation may be caused by selection effects, similar to those explaining larger  $\lambda_{\max}$  for nearby stars: a large proportion of strongly reddened stars are distant stars with small ratio of  $E_{B-V}$  to distance. The light of such stars passes predominantly

FIG. 9.—The relationship between the maximum interstellar polarization  $p_{\max}$  (%) and color excess  $E_{B-V}$ . A straight line corresponds to  $p_{\max}/E_{B-V} = 9.0$ . The symbols are the same as in fig. 6.

FIG. 10.—The wavelength dependence of the polarization position angle  $\theta$  observed with the multichannel polarimeter-photometer for some early-type main-sequence stars (a) and for supergiants and giants (b). The mean errors are indicated. The zero points  $\theta_0$  of the position angle scale are arbitrary.

through low-density dust clouds, characterized by small  $\lambda_{\max}$  (Carrasco *et al.* 1973).

The relationship between  $\lambda_{\max}$  and  $p_{\max}/E_{B-V}$  is illustrated in table 7. Only stars with  $E_{B-V} \geq 0.30$  mag ( $\geq 0.40$  mag if  $E_{B-V}$  is followed by a colon in table 5) were used. The coefficient of correlation between  $p_{\max}/E_{B-V}$  and  $E_{B-V}$  is  $-0.29$  while that between  $p_{\max}/E_{B-V}$  and  $\lambda_{\max}$  is  $-0.05$ . Therefore, the coefficient of partial correlation between  $p_{\max}/E_{B-V}$  and  $\lambda_{\max}$  relative to  $E_{B-V}$  is  $-0.12 \pm 0.07$ . The reality of this correlation is indicated more convincingly by the dependence of median values of  $\lambda_{\max} + 0.03 E_{B-V}$  (cf. eq. [13]) on  $p_{\max}/E_{B-V}$  shown in table 7: for  $p_{\max}/E_{B-V} < 5.0$  the median value of  $\lambda_{\max} + 0.03 E_{B-V}$  is larger by  $0.023 \mu$  than for  $p_{\max}/E_{B-V} > 5.0$ . The negative correlation between  $p^V/p^B$  and  $p^V/E_{B-V}$  was discovered by Kruszewski (1962) as a result of the earliest systematic search for variations in wavelength dependence of interstellar polarization, which were first noticed by Behr (1959).

The ratio  $p/E_{B-V}$  is a measure of alignment of interstellar dust grains by galactic magnetic field. If alignment is not complete,  $\lambda_{\max}$  is expected to be larger in a stronger magnetic field, capable of aligning larger grains (Davis 1959). This is contrary to the present observations which indicate a very poor negative correlation between  $\lambda_{\max}$  and  $p_{\max}/E_{B-V}$ . We may therefore conclude that magnetic field has negligible influence on  $\lambda_{\max}$  which, like  $R$ , is determined mainly by the average size of dust grains. How little influence the magnetic alignment has on wavelength dependence of light scattering by dust grains is also indicated by lack of correlation between the ratio of color excesses  $E_{U-B}/E_{B-V}$  and the ratio  $p/E_{B-V}$  (Serkowski 1963).

The relationship between the maximum percentage polarization  $p_{\max}$  and the color excess  $E_{B-V}$  is shown in figure 9. The stars with uncertain  $E_{B-V}$ , followed by a colon in table 5 or having spectral type F or later, are not plotted. The ratio  $p_{\max}/E_{B-V}$

\* Our circular polarization  $q$  is equivalent to  $V/I$  of Martin 1974.

rarely exceeds 9.0, which value is represented as a straight line in figure 9. The stars lying slightly to the left of this line suggest that the intrinsic colors by Schmidt-Kaler (1965), used for calculating  $E_{B-V}$ , should be diminished for B-type stars by at least 0.02 mag. The intrinsic colors of B-type supergiants would thus become close to those derived by Serkowski (1963). To clarify this point, repeating the MK classification and photometry of the most strongly deviating stars, HD 7252, 8965, 13267, 38771, 46769, 142919, and 161840, would be desirable.

The position angles of polarization show a pronounced wavelength dependence for a number of stars observed with a multichannel polarimeter. Such wavelength dependence is expected when the light traverses regions with various values of  $\lambda_{\max}$  and with various orientation of dust grains (cf. Coyne 1974). In many cases, however, wavelength dependence of position angle is caused by superposition of intrinsic and interstellar polarization (Serkowski 1970a). We may see in figure 10, showing some examples of this wavelength dependence, that early-type main-sequence stars have often an extreme value of position angle around the blue spectral region where the intrinsic polarization of Be stars has its maximum. On the other hand, supergiants usually show monotonic change in position angle, as wavelength dependence of their intrinsic polarization does not have a sharp peak.

The wavelength  $\lambda_{\max}$  seems to coincide with the

wavelength at which the wavelength dependence of interstellar circular polarization changes sign (Martin 1974). This is supported by the observations of circular polarization, listed with their mean errors in table 8, made by Serkowski during 1973 July with the 152-cm telescope on Mount Palomar. The near-infrared spectral region ( $\lambda_{\text{eff}} \approx 0.845 \mu$ ) was defined by a Schott RG 8 filter 1.5 mm thick and S1 photomultiplier. The quarter-wave plate was manually rotated by  $90^\circ$  in front of a rapidly rotating achromatic half-wave plate in a polarimeter described by Serkowski (1974).

The largest known values of the interstellar circular polarization were found in the near-infrared for two stars with exceptionally low values of  $\lambda_{\max}$ : star No. 12 in the VI Cygni association ( $\lambda_{\max} = 0.45 \mu$ ), and HD 204827 ( $\lambda_{\max} = 0.46 \mu$ ). The observations of circular polarization for the latter star in the  $B$  and  $U$  spectral regions of the  $UBV$  system suggest that circular polarization changes its sign around  $0.43 \mu$ .

We are grateful to the National Science Foundation for financing the computations made for this paper at the University of Arizona. Jonathan Gradie and Thomas Kunkle made most of the calculations. One of the authors (K. S.) is grateful to Dr. H. W. Babcock, Director of Hale Observatories, for providing the telescope time, and to Dr. S. E. Strom for helpful discussions.

## APPENDIX

### ADDITIONAL POLARIMETRIC OBSERVATIONS

Polarimetric observations of a number of southern stars, many of them in open clusters, are listed in table A1. They were made with a two-channel polarimeter in a search for stars suitable for a study of wavelength dependence of interstellar polarization. Table A1 contains also polarimetry of Sco X-1 and the open clusters Praesepe and M67. Assuming the maximum ratio of degree of polarization to color excess given by Schmidt-Kaler (1958), we find the lower limits of reddening:

$$E_{B-V} \geq 0.009 \text{ mag for Praesepe,}$$

$$E_{B-V} \geq 0.019 \text{ mag for M67.}$$

Similar estimates for several globular clusters are given in table A2. All the observations in table A2 were made with a two-channel polarimeter without filter, using an aperture  $80''$  in diameter for globular clusters, and about  $20''$  for galaxies which were observed in 1969 July. A small but significant linear polarization was found for some galaxies, in particular for NGC 7041. (See note added in proof.)

*Note added in proof.*—Our results for Praesepe agree with those of T. Markkanen (*Astr. and Ap.*, **35**, 297 [1974]), who obtained  $p = 0.13 \pm 0.04\%$ ,  $\theta = 55^\circ$  as an average for 17 stars.
